Abstract: The continuous obstacle of Dictyophora indusiata has become one of the main factors affecting the healthy development of D. indusiata. In order to study the effects of continuous cropping of D. indusiata on the soil environment, four treatments were used in this study: no planted (CK), planted for 1 year (1Y), continuous cropping for 2 years (2Y) and continuous cropping for 3 years (3Y), to determine the yield of D. indusiata, soil physical and chemical properties, microbial content and enzyme activity. The results showed that the yield of D. indusiata decreased significantly, which will cause the crop growth obstacles (Zhang et al. 2016). Continuous cropping can significantly affect the dry matter production and accumulation process of plants, and also significantly affect the distribution and distribution rate of assimilated products to economic organs after flowering, which may be an important cause of serious decline in crop economic yield under continuous cropping system. In continuous cropping, the structure of soil aggregate is destroyed, resulting in soil hardening and poor buffering (Wan 2011). For example, the continuous cropping of Gossypium spp will increase the soil specific gravity and bulk density, decrease the porosity (Chai et al. 2008). The soil enzyme activity can also reflect the transformation ability of nutrient elements and the change of soil biological activity in the soil ecosystem, which can be used to measure the health status of the soil. The activities of sucrase, urease and phosphatase were decreased with the extension of continuous cropping time (Sun et al. 2010; Dou et al. 2016). This is also found in the study of Poria cocos (Yu et al. 2009). Continuous cropping can disturb the ecological balance of soil microbes and change the population and function of soil microbes, which can directly affect the growth of crops (Yu et al. 2009; Chen et al. 2012). After 4 years of continuous cropping (Burley tobacco), the diversity of soil bacterial community decreased significantly, and the bacterial community structure became single (Chen et al. 2010). The cultivation of D. indusiata needs fertile and loose soil, high humus content, good permeability and hard to harden, the soil under the bamboo forest is very suitable (Zhen et al. 2001).

Keywords: Dictyophora indusiata, Continuous cropping, Soil physicochemical properties, Soil microbial biomass, Soil enzyme activity.

1. Introduction

Dictyophora indusiata is a kind of edible and medicinal fungus (Cai et al. 2015). It has high nutritional value, including a large number of proteins, fats, total sugars, cellulose and polysaccharides, and also contains 8 kinds of amino acids necessary for human body (Ker et al. 2011). In recent years, the cultivation of D. indusiata has developed rapidly, the scale of cultivation expanded and yield increased continuously, the cultivation of D. indusiata has become an important economic source and regional characteristic industry for farmers (Lin et al. 2011). The cultivated land resources in China are relatively scarce, so making full use of the space under all kinds of bamboo forest and developing the edible fungus under the bamboo forest can alleviate the difficulty of the cultivated land shortage, which is also an important and potential development direction of the edible fungus industry at present (Lv et al. 2012). At present, the development of D. indusiata under the bamboo forest has encountered continuous cropping obstacles, after planting D. indusiata under the same bamboo forest for many years, even under the conventional management conditions, the production, quality and growth condition of D. indusiata planted in the second year of the same plot will decrease (Lv et al. 2012; Chang et al. 2013).

The reason of crop continuous cropping obstacle is mainly from soil, and it is the result of many comprehensive effects (Hou et al. 2016). After continuous cropping, the soil nutrients will change unevenly, which will cause the crop growth obstacles (Zhang et al. 2016; Chen et al. 2018). Continuous cropping of Panax notoginseng will enrich inorganic elements in soil and aggravate soil diseases (Liu et al. 2014). Studies on crops such as flue-cured tobacco (Ye et al. 2011; Gu et al. 2013), soybean (Wang et al. 1997; Xu et al. 1999) and peanut (Wu et al. 2006; Wang et al. 2011) have confirmed that continuous cropping can significantly affect the dry matter production and accumulation process of plants, and also significantly affect the distribution and distribution rate of assimilated products to economic organs after flowering, which may be an important cause of serious decline in crop economic yield under continuous cropping system. In continuous cropping, the structure of soil aggregate is destroyed, resulting in soil hardening and poor buffering (Wan 2011). For example, the continuous cropping of Gossypium spp will increase the soil specific gravity and bulk density, decrease the porosity (Chai et al. 2008). The soil enzyme activity can also reflect the transformation ability of nutrient elements and the change of soil biological activity in the soil ecosystem, which can be used to measure the health status of the soil. The activities of sucrase, urease and phosphatase were decreased with the extension of continuous cropping time (Sun et al. 2010; Dou et al. 2016). This is also found in the study of Poria cocos (Yu et al. 2009). Continuous cropping can disturb the ecological balance of soil microbes and change the population and function of soil microbes, which can directly affect the growth of crops (Yu et al. 2009; Chen et al. 2012). After 4 years of continuous cropping (Burley tobacco), the diversity of soil bacterial community decreased significantly, and the bacterial community structure became single (Chen et al. 2010). The cultivation of D. indusiata needs fertile and loose soil, high humus content, good permeability and hard to harden, the soil under the bamboo forest is very suitable (Zhen et al. 2001). All the raw
materials left after the production of D. indusiata return to the soil, the main components of these raw materials are difficult to decompose lignin, etc., which can be used as raw materials for soil improvement and effectively improve the soil texture. However, under continuous cropping conditions, the accumulation of these lignin will be difficult to decompose by soil microorganisms in time, resulting in the decline of soil texture, which will affect the production of D. indusiata, and will change the growth conditions of trees and affect the growth of bamboo.

In some areas, the problem of continuous cropping obstacles has seriously affected the healthy development of D. indusiata industry (Shi 2018; Chen et al. 2017; Jiang 2011). In view of this, the yield and soil physicochemical properties and microbial diversity of D. indusiata under continuous D. indusiata under bamboo forest were studied. The purpose is to reveal the influence of continuous cropping of D. indusiata on soil structure, and to reveal the reasons for the change of soil structure in the process of continuous cropping of D. indusiata in combination with the analysis of soil physical and chemical properties, to provide a theoretical basis for the comprehensive analysis of the obstacles of continuous cropping of D. indusiata.

2. Materials and Methods

2.1 Experimental Materials

The experimental site is located at Lanfeng forest farm (105°33.312′E, 29°17.031′N), Rongchang city, Chongqing province, China. The altitude is 480 m, and the soil is mountain yellow soil with mean precipitation of 1099 mm, annual average temperature is 17.8℃, annual total accumulated temperature is 6482℃. The frostless season more than 327 days, monthly extreme maximum temperature is 39.9℃ (1972), and monthly extreme minimum temperature is -3.4℃ (1975), the daily mean temperature is stable through 12℃, which is 265 days. The annual average sunshine time is 1282 hours, and the annual rainfall is 1111.8 mm. The average DBH of bamboo forest was 7.9 cm, and the average density of standing bamboo was 3780 plants/hm².

2.2 Experimental Design

This experiment period was continued 3 years, and the plot was designed in 2017, set up a sample land with 30 m x 30 m, continuous planting D. indusiata for 3 years treatment. Set up another sample land with 30 m x 30 m in 2018, continuous planting D. indusiata for 2 years. Set up the same size sample land in 2019, planting D. indusiata for 1 years. Set up a 30 m x30 m blank plot as control, the spacing of each plot was more than 10 m, and set a buffer zone with a width of 5 m was set at the edge of each plot. There were four treatments in the experiment: the unplanting plot (CK), planting one year in 2019 (1Y), continuous cropping two years from 2018 to 2019 (2Y), and continuous cropping three years from 2017 to 2019 (3Y). The quality and yield of D. indusiata was recorded for 3 consecutive years, and soil samples were collected in the second wave period of D. indusiata in 2019. Five sampling points were randomly set with the shape of "S", and using a sterilized shovel to obtain the surface soil samples in the range of 0 cm to 15 cm in the rhizosphere of D. indusiata, the rhizosphere soil adhered to the root surface was obtained by buffeting method and mixed. Finally, 5 randomly sampled points were mixed as a soil sample, and CK was collected in 2017. The soil samples were divided into two parts: one of them was screened by 2 mm sieve, to determine the physical and chemical properties of the soil after air drying; the other was used to pick up the stones and sundries and take them back to the laboratory for preservation at -20℃, to analyze the enzyme activity and microorganism.

2.3 Experimental Methods

Soil samples were air-dried and all soil physicochemical properties were determined by dry weight (Bao 2000). Soil pH shall be determined with acidimeter according to the water soil ratio of 2:5:1. Determination of soil organic carbon (SOC) and organic matter (SOM) by H₂SO₄-K₂Cr₂O₇ wet oxidation method. Soil total nitrogen (TN) was determined using Kjeldahl’s method, available nitrogen (AN) was determined using the alkali-hydrolytic diffusion method. Soil total phosphorus (TP) and available phosphorus (AP) were determined using molybdenum antimony contrast method. Soil total potassium (TK) and available potassium (AK) were determined by flame spectrophotometer method. Soil urease activity was measured using sodium phenol-sodium hypochlorite colorimetric method, phosphatase activity was measured using disodium phosphate colorimetric method, invertase activity was measured using 3,5-Dinitrosalicylic acid colorimetry method, protease activity was measured using chironolactone colorimetric method, catalase activity was measured using permanganate titration method, peroxidase and polyphenol oxidase activity were measured using pyrogallol colorimetry method. Soil microbial biomass was determined using phospholipid fatty acid (PLFA) analysis by gas chromatography mass spectrometry. The determination of soil physical and chemical properties and microbial diversity was completed in the South economic forest product quality inspection center of Subtropical Forestry Research Institute, China Academy of Forestry Sciences.

2.4 Statistical Analysis.

Soil physical and chemical properties and bacterial diversity index were analyzed by Duncan's new method (P < 0.05) based on SPSS 22.0 software. Adopt the form of average value ± standard error, and different letters in the same column showed significant differences.

3. Results and Analysis

3.1 Quality and Yield of D. indusiata.

The data show that continuous cropping of D. indusiata has a certain influence on quality and yield of D. indusiata. There was no significant difference in the length of D. indusiata treated with the increase of continuous cropping years. The
fresh weight of the 3Y decreased significantly compared with 1Y and 2Y, and decreased by 7.77% compared with 1Y, decreased by 7.40% compared with 2Y, but there was no significant difference between 1Y and 2Y. The dry weight of *D. indusiata* decreased with the increase of continuous cropping years. There was no significant difference in water rate between different treatments. The yield of *D. indusiata* showed the minimum value at 3Y, which was 40.15 kg/ha², significantly lower than 1Y and 2Y.

### 3.2 Physicochemical Properties of Soil

As shown in table 2, compared with CK, the soil pH decreased significantly after continuous cropping of *D. indusiata*, the pH value of 1Y, 2Y and 3Y decreased by 8.74%, 11.66% and 13.72%, respectively. The SOM content of 1Y, 2Y and 3Y increased significantly compared with CK, but there was no significant difference between 1Y and 2Y. The AP content of 3Y was 20.61% higher than that of CK and 1Y, respectively, and ranked as: 1Y > 2Y > 3Y > CK, the maximum value was 163.7 mg/kg at 1Y.

Note: Data shows average value ± standard errors, and different letters indicate significant differences between treatments (*P* < 0.05), similarly hereinafter.

### 3.3 N/P, C/N and N/P Ratio in Soil

The C/N ratio of 1Y was 12.28% higher than that of CK, but it did not reach the significant level (*P* < 0.05). The C/N ratio of 2Y was 19.55% and 6.48% higher than that of CK and 1Y, respectively. The C/N ratio of 3Y was 23.01% and 9.56% higher than that of CK and 1Y, respectively, and there was no significant difference with 2Y. The C/P ratio of 1Y, 2Y and 3Y increased by 27.39%, 30.90% and 48.73%, respectively, compared with CK, and all of them reached significant level (*P* < 0.05). C/P ratio of 3Y also increased significantly compared with 1Y and 2Y, and there was no significant difference between 1Y and 2Y. The N/P ratio increased significantly after continuous cropping of *D. indusiata*. Compared with CK, the N/P ratio of 1Y, 2Y and 3Y increased by 13.29%, 9.49% and 20.61%, respectively, and ranked as: 3Y > 1Y > 2Y > CK.

### 3.4 Soil Enzyme Activities

The soil enzyme activity increased first and then decreased with the increase of continuous cropping years (table 3). Soil urease, catalase, peroxidase, succase, phosphatase and protease activities had maximum values at 1 Y, which increased by 74.14%, 35.80%, 39.19%, 62.41%, 13.41% and 20.13%, respectively, compared with CK, and reached significant levels (*P* < 0.05). The catalase and peroxidase activities of 1Y and 3Y were higher than those of CK, but decreased with the increase of continuous cropping years. There was no significant difference between CK, 2Y and 3Y in urease activity, but significantly lower than 1Y (*P* < 0.05). The urease, succase and phosphatase activities of 3Y decreased by 9.39%, 12.97% and 12.15%, respectively, compared with CK. There was no significant difference in the activities of polyphenoloxidase between 1Y, 2Y and 3Y, but they were 41.72%, 48.73% and 45.61% higher than that of the control respectively, and reached significant level (*P* < 0.05).
3.5 Soil Microbial Biomass

The biomasses of bacteria, fungi and the total microorganisms in soil were increased after continuous cropping of *D. indusiata* (Table 4). The bacterial and total microorganisms biomass in soil were increased first and then decreased with the increase of continuous cropping years, ranked as: 1Y > 2Y > 3Y > CK. Compared with CK, the bacterial biomass of 1Y, 2Y and 3Y were increased by 40.10%, 20.99% and 9.30%, respectively, the total microorganisms biomass was increased by 52.52%, 39.08% and 29.78%, respectively, and reached significant level (*P* < 0.05). The biomass of soil actinomycetes was higher than that of CK at 1Y, and significantly increased by 29.46%. There was no significant difference between the actinomycetes biomass in 2Y and CK, but it was significantly lower than 1Y. Soil fungi biomass was increased with the increase of continuous cropping years, ranked as: 3Y > 2Y > 1Y > CK, and reached significant level (*P* < 0.05).

3.6 Proportion of Soil Microbial Species

Figure 2 shows the proportion of bacteria and actinomycetes in soil were decreased with the increase of continuous cropping years, had the minimum at 3Y, which decreased by 15.83% and 71.76%, respectively, compared with CK, and reached significant levels (*P* < 0.05). In contrast to bacteria and actinomycetes, the proportion of fungi in soil increased significantly with the increase of continuous cropping years (*P* < 0.05). Compared with CK, the fungi proportion of 1Y, 2Y and 3Y increased by 14.85%, 51.98% and 91.09%, respectively. With the increase of continuous cropping years, the bacteria/fungi ratio in soil gradually decreased, and minimum at 3Y, which were 55.95%, 44.94% and 23.07% lower than CK, 1Y and 2Y, respectively, and reached significant level (*P* < 0.05). The bacteria/actinomycetes ratio in soil was significantly higher than that of other treatments at 3Y, and there was no significant difference among CK, 1Y and 2Y (*P* > 0.05).

4. Discussion

4.1 Continuous-cropping of *D. indusiata* on Soil Physicochemical Properties

The species and contents of the original mineral nutrients in the soil environment are fixed, and the crops have a specific absorption law to it. With the increase of continuous cropping years, the elements needed more by crops will be reduced in soil, while the elements that are not absorbed by crops will be enhanced, which causing the imbalance of soil nutrients (Ma et al. 2016). The TN, AN, TP, AP, TK and AK of *Solanum tuberosum* were decreased with the increase of continuous cropping years (Du et al. 2012). With the increase of continuous cropping years of *Cucumis sativus* in facility cultivation, the soil pH decreased, the contents of organic matter and available Fe increased, while the contents of available Mn, Zn and other trace elements decreased (Zhang 2017). In this experiment, soil pH was decreased with the increase of continuous cropping years, but it was consistent with the studies of *Phallus echinovolvatus*. Soil pH is mainly related to the content of soil organic acids, and it is possible to secrete a large amount of organic acids during the growth of *D. indusiata*, but with the increase of continuous cropping years, it increased the accumulation of soil organic acids, resulting in the decrease of soil pH value. Compared with CK, the content of AN decreased at 2Y and 3Y, but the contents of soil SOM, SOC, TN, TP, AN, AP and AK were increased. Compared with the unplanted soil, it was found that the contents of organic matter and mineral elements in the soil were higher than those in the control (Liang et al. 2019). This may be due to the *D. indusiata* belongs to saprophytic bacteria, and the organic matter and mineral elements of the soil increase after planting. Soil AN, AP and AK contents reached the highest at 1Y, but decreased after continuous cropping, and their soil TN, TP and TK reached the highest at 3Y. This shows that after planting *D. indusiata* one year, the TN accumulation of soil increased the nitrification of soil, which led to the increase of soil alkali-hydrolyzed nitrogen content, while after continuous cropping, the oxygen consumption of soil was greatly increased, denitrification was enhanced, nitrate was reduced in large quantities, resulting in the loss of soil alkali-hydrolyzed nitrogen. The ratio of C, N and P in the soil increased after the continuous cropping of *D. indusiata*, which...
resulted in the imbalance of the ratio of C, N and P in the soil, and further directly reduced the yield of *D. indusiata*, which indicated that continuous cropping of *D. indusiata* had an adverse effects on the balance and synergy of the main nutrients in the soil, it was one of the main causes of soil degradation and the lower yield of *D. indusiata*.

4.2 Continuous-cropping of *D. indusiata* on Soil Microbial Biomass

After continuous cropping, the management mode was basically consistent, which led to the directional change of soil environment, and caused the loss of some nutrient elements, the harmful microorganism increased year by year, the beneficial microorganism decreased year by year, and finally destroyed the soil health level (Ma et al. 2004). It has been found that with the increase of continuous cropping years, the biomass of bacteria in soil microbe was decreased, but contrary to fungi biomass, which led to multiply some parasitic bacteria, and finally aggravates crop diseases (Guo et al. 2016). In this experiment, the biomasses of bacteria, actinomycetes, fungi and the total microorganisms in 1Y were higher than CK. With the increase of continuous cropping years, the biomasses of bacteria and actinomycetes and total microorganisms had a reduce trend, while the biomasses of fungi increased. This may be because the soil nutrient availability increased after the planting of *D. indusiata*, thus the soil microbial biomass increased, and with the increase of continuous cropping years, the formation of specific soil environment and Rhizosphere conditions affects the reproduction and activity of soil and rhizosphere microorganisms, resulted the fungal enrichment, soil fertility changes. After continuous cropping, the proportion of bacteria/fungi decreased and the proportion of fungi increased, and bacterial soil transformed into fungal soil. Some studies have shown that fungal soil as a markers of soil fertility failure, and bacterial soil to be a biological indicator of soil fertility improvement (Li et al. 2006). As similar to previous studies, continuous cropping of *Ophiopogon japonicus* decreased the biomasses of bacteria and actinomycetes in soils, while the biomasses of fungi increased with the increase of continuous cropping years (Zhang et al. 2016). Analyzed the changing trend of yield by sterilizion the soil of *Glycine max* every time, and found that the main reason for the reduction of *G. max* after continuous cropping was the change of growth environment (Hassan et al. 1989). After continuous cropping of *Citrullus lanatus*, the soil microflora also changed, with the increase of continuous cropping years, the biomasses of bacteria and actinomycetes in soil increased first and then decreased, while the biomasses of fungi decreased first and then increased (Zhao et al. 2008).

4.3 Continuous-cropping of *D. indusiata* on Soil Enzyme Activities

Soil enzyme activity is an important index to evaluate the soil fertility, and the function of soil enzyme can not be separated from the material circulation of C, N, P, K and other elements (Cao et al. 2008). Soil enzymes mainly come from microorganisms, plant root exudates and the release of soil animal and plant residues. In addition, soil enzyme activity is also affected by many factors, such as environment and fertilizer, and there is a relationship between substrate and product of various soil enzymes (Qiu et al. 2004). In this experiment, the soil enzyme activity of 1Y was higher than that of CK, but decreased in different degree with the increase of continuous cropping years except polyphenoloxidase. The decrease of soil enzyme activity may be related to the fungi properties of *D. indusiata*, and SOC releases specific plant nutrients under the action of various enzymes. Studies have shown a positive correlation between soil enzyme activity and soil nutrient availability (Chen et al. 2015). In this study, the soil nutrient availability was decreased after continuous cropping, which may lead to the decrease of soil enzyme activity. Studies have shown that the correlation between soil microbial biomass and soil phosphatase, catalase and urease activity has reached an extremely significant or significant level, which indicates that soil enzyme activity is related to soil microbial biomass (Zhao et al. 2010). The total microorganisms decreased with the increase of continuous cropping years, which also may be one of the reasons for the decrease of soil enzyme activity. The changes of soil enzyme activity were different with cropping of different plants. After continuous cropping of *Rehmannia glutinosa*, the activities of urease, protease, polyphenoloxidase, sucrase and cellulase in soil showed an increasing trend, but the catalase activity in soil showed a decreasing trend (Chen et al. 2007). In the study of soil enzyme activity of *Poria cocos*, the activity of urease, acid phosphatase, dehydrogenase and catalase in soil were decreased with the increase of continuous cropping years (Yu et al. 2009).

5. Conclusion

The contents of soil SOC, TN, TP, TK, the C/N and C/P ratio were improved by continuous cropping of *D. indusiata*, besides, the trend was increasing with the increase of continuous cropping years. The nutrients availability and pH in soil were decreased with the increase of continuous cropping years. The continuous cropping of *D. indusiata* transformed the soil from bacterial to fungal, the contents of bacteria, actinomycetes and total microorganisms were decreased with the increase of continuous cropping years, while the content of fungi increased. Continuous cropping could reduce the soil urease, catalase, peroxidase, sucrase, phosphatase and protease activity, but it has no significant effect on soil polyphenol oxidase. The results showed that the continuous cropping of *D. indusiata* will reduce the soil texture, it not conducive to the production of *D. indusiata* under bamboo forests.
